QUIC-LB: Generating Routable QUIC Connection IDs
draft-ietf-quic-load-balancers-06

Abstract

The QUIC protocol design is resistant to transparent packet inspection, injection, and modification by intermediaries. However, the server can explicitly cooperate with network services by agreeing to certain conventions and/or sharing state with those services. This specification provides a standardized means of solving three problems: (1) maintaining routability to servers via a low-state load balancer even when the connection IDs in use change; (2) explicit encoding of the connection ID length in all packets to assist hardware accelerators; and (3) injection of QUIC Retry packets by an anti-Denial-of-Service agent on behalf of the server.

Table of Contents

1. Introduction

QUIC packets [QUIC-TRANSPORT] usually contain a connection ID to allow endpoints to associate packets with different address/ port 4-tuples to the same connection context. This feature makes connections robust in the event of NAT rebinding. QUIC endpoints usually designate the connection ID which peers use to address packets. Server-generated connection IDs create a potential need for out-of-band communication to support QUIC.

QUIC allows servers (or load balancers) to designate an initial connection ID to encode useful routing information for load balancers. It also encourages servers, in packets protected by cryptography, to provide additional connection IDs to the client. This allows clients that know they are going to change IP address or port to use a separate connection ID on the new path, thus reducing linkability as clients move through the world.

There is a tension between the requirements to provide routing information and mitigate linkability. Ultimately, because new connection IDs are in protected packets, they must be generated at the server if the load balancer does not have access to the connection keys. However, it is the load balancer that has the context necessary to generate a connection ID that encodes useful routing information. In the absence of any shared state between load balancer and server, the load balancer must maintain a relatively expensive table of server-generated connection IDs, and will not route packets correctly if they use a connection ID that was originally communicated in a protected NEW_CONNECTION_ID frame.

This specification provides common algorithms for encoding the server mapping in a connection ID given some shared parameters. The mapping is generally only discoverable by observers that have the parameters, preserving unlinkability as much as possible.

Aside from load balancing, a QUIC server may also desire to offload other protocol functions to trusted intermediaries. These intermediaries might include hardware assist on the server host itself, without access to fully decrypted QUIC packets. For example, this document specifies a means of offloading stateless retry to counter Denial of Service attacks. It also proposes a system for self-encoding connection ID length in all packets, so that crypto offload can consistently look up key information.

While this document describes a small set of configuration parameters to make the server mapping intelligible, the means of distributing these parameters between load balancers, servers, and other trusted intermediaries is out of its scope. There are numerous well-known infrastructures for distribution of configuration.

1.1. Terminology

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC 2119 [RFC2119].

In this document, these words will appear with that interpretation only when in ALL CAPS. Lower case uses of these words are not to be interpreted as carrying significance described in RFC 2119.

In this document, "client" and "server" refer to the endpoints of a QUIC connection unless otherwise indicated. A "load balancer" is an intermediary for that connection that does not possess QUIC connection keys, but it may rewrite IP addresses or conduct other IP or UDP processing. A "configuration agent" is the entity that determines the QUIC-LB configuration parameters for the network and leverages some system to distribute that configuration.

Note that stateful load balancers that act as proxies, by terminating a QUIC connection with the client and then retrieving data from the server using QUIC or another protocol, are treated as a server with respect to this specification.

For brevity, "Connection ID" will often be abbreviated as "CID".

1.2. Notation

All wire formats will be depicted using the notation defined in Section 1.3 of [QUIC-TRANSPORT]. There is one addition: the function len() refers to the length of a field which can serve as a limit on a different field, so that the lengths of two fields can be concisely defined as limited to a sum, for example:

x(A..B) y(C..B-len(x))

indicates that x can be of any length between A and B, and y can be of any length between C and B provided that (len(x) + len(y)) does not exceed B.

The example below illustrates the basic framework:

```
Example Structure {
  One-bit Field (1),
  7-bit Field with Fixed Value (7) = 61,
  Field with Variable-Length Integer (i),
  Arbitrary-Length Field (..),
  Variable-Length Field (8..24),
  Variable-Length Field with Dynamic Limit (8..24-len(Variable-Length Field)),
  Field With Minimum Length (16..),
  Field With Maximum Length (..128),
  [Optional Field (64)],
  Repeated Field (8) ...,
}
```

Figure 1: Example Format

2. Protocol Objectives

2.1. Simplicity

QUIC is intended to provide unlinkability across connection migration, but servers are not required to provide additional connection IDs that effectively prevent linkability. If the coordination scheme is too difficult to implement, servers behind load balancers using connection IDs for routing will use trivially linkable connection IDs. Clients will therefore be forced to choose between terminating the connection during migration or remaining linkable, subverting a design objective of QUIC.

The solution should be both simple to implement and require little additional infrastructure for cryptographic keys, etc.

2.2. Security

In the limit where there are very few connections to a pool of servers, no scheme can prevent the linking of two connection IDs with high probability. In the opposite limit, where all servers have many connections that start and end frequently, it will be difficult to associate two connection IDs even if they are known to map to the same server.

QUIC-LB is relevant in the region between these extremes: when the information that two connection IDs map to the same server is helpful to linking two connection IDs. Obviously, any scheme that transparently communicates this mapping to outside observers compromises QUIC’s defenses against linkability.

Though not an explicit goal of the QUIC-LB design, concealing the server mapping also complicates attempts to focus attacks on a specific server in the pool.

3. First CID octet

The first octet of a Connection ID is reserved for two special purposes, one mandatory (config rotation) and one optional (length self-description).

Subsequent sections of this document refer to the contents of this octet as the "first octet."

3.1. Config Rotation

The first two bits of any connection ID MUST encode an identifier for the configuration that the connection ID uses. This enables incremental deployment of new QUIC-LB settings (e.g., keys).

When new configuration is distributed to servers, there will be a transition period when connection IDs reflecting old and new configuration coexist in the network. The rotation bits allow load balancers to apply the correct routing algorithm and parameters to incoming packets.

Configuration Agents SHOULD deliver new configurations to load balancers before doing so to servers, so that load balancers are ready to process CIDs using the new parameters when they arrive.

A Configuration Agent SHOULD NOT use a codepoint to represent a new configuration until it takes precautions to make sure that all connections using CIDs with an old configuration at that codepoint have closed or transitioned.

Servers MUST NOT generate new connection IDs using an old configuration after receiving a new one from the configuration agent. Servers MUST send NEW_CONNECTION_ID frames that provide CIDs using the new configuration, and retire CIDs using the old configuration using the "Retire Prior To" field of that frame.

It also possible to use these bits for more long-lived distinction of different configurations, but this has privacy implications (see Section 11.3).

3.2. Configuration Failover

If a server has not received a valid QUIC-LB configuration, and believes that low-state, Connection-ID aware load balancers are in the path, it SHOULD generate connection IDs with the config rotation bits set to ’11’ and SHOULD use the "disable_active_migration" transport parameter in all new QUIC connections. It SHOULD NOT send NEW_CONNECTION_ID frames with new values.

A load balancer that sees a connection ID with config rotation bits set to ’11’ MUST revert to 5-tuple routing.

3.3. Length Self-Description

Local hardware cryptographic offload devices may accelerate QUIC servers by receiving keys from the QUIC implementation indexed to the connection ID. However, on physical devices operating multiple QUIC servers, it is impractical to efficiently lookup these keys if the connection ID does not self-encode its own length.

Note that this is a function of particular server devices and is irrelevant to load balancers. As such, load balancers MAY omit this from their configuration. However, the remaining 6 bits in the first octet of the Connection ID are reserved to express the length of the following connection ID, not including the first octet.

A server not using this functionality SHOULD make the six bits appear to be random.

3.4. Format

```
First Octet {
  Config Rotation (2),
  CID Len or Random Bits (6),
}
```

Figure 2: First Octet Format

The first octet has the following fields:

Config Rotation: Indicates the configuration used to interpret the CID.

CID Len or Random Bits: Length Self-Description (if applicable), or random bits otherwise. Encodes the length of the Connection ID following the First Octet.

4. Load Balancing Preliminaries

In QUIC-LB, load balancers do not generate individual connection IDs for servers. Instead, they communicate the parameters of an algorithm to generate routable connection IDs.

The algorithms differ in the complexity of configuration at both load balancer and server. Increasing complexity improves obfuscation of the server mapping.

This section describes three participants: the configuration agent, the load balancer, and the server. For any given QUIC-LB configuration that enables connection-ID-aware load balancing, there must be a choice of (1) routing algorithm, (2) server ID allocation strategy, and (3) algorithm parameters.

Fundamentally, servers generate connection IDs that encode their server ID. Load balancers decode the server ID from the CID in incoming packets to route to the correct server.

There are situations where a server pool might be operating two or more routing algorithms or parameter sets simultaneously. The load balancer uses the first two bits of the connection ID to multiplex incoming DCIDs over these schemes (see Section 3.1).

4.1. Non-Compliant Connection IDs

QUIC-LB servers will generate Connection IDs that are decodable to extract a server ID in accordance with a specified algorithm and parameters. However, QUIC often uses client-generated Connection IDs prior to receiving a packet from the server.

These client-generated CIDs might not conform to the expectations of the routing algorithm and therefore not be routable by the load balancer. These are called "non-compliant DCIDs":

* The config rotation bits (Section 3.1) may not correspond to an active configuration. Note: a packet with a DCID that indicates 5-tuple routing (see Section 3.2) is always compliant.

* The DCID might not be long enough for the decoder to process.

* The extracted server mapping might not correspond to an active server.

All other DCIDs are compliant.

Load balancers MUST forward packets with compliant DCIDs to a server in accordance with the chosen routing algorithm.

Load balancers SHOULD drop packets with non-compliant DCIDs in a short header.

The routing of long headers with non-compliant DCIDs depends on the server ID allocation strategy, described in Section 4.3. However, the load balancer MUST NOT drop these packets, with one exception.

Load balancers MAY drop packets with long headers and non-compliant DCIDs if and only if it knows that the encoded QUIC version does not allow a non- compliant DCID in a packet with that signature. For example, a load balancer can safely drop a QUIC version 1 Handshake packet with a non-compliant DCID, as a version 1 Handshake packet sent to a QUIC-LB compliant server will always have a server-generated compliant CID. The prohibition against dropping packets with long headers remains for unknown QUIC versions.

Furthermore, while the load balancer function MUST NOT drop packets, the device might implement other security policies, outside the scope of this specification, that might force a drop.

Servers that receive packets with noncompliant CIDs MUST use the available mechanisms to induce the client to use a compliant CID in future packets. In QUIC version 1, this requires using a compliant CID in the Source CID field of server-generated long headers.

4.2. Arbitrary Algorithms

There are conditions described below where a load balancer routes a packet using an "arbitrary algorithm." It can choose any algorithm, without coordination with the servers, but the algorithm SHOULD be deterministic over short time scales so that related packets go to the same server. The design of this algorithm SHOULD consider the version-invariant properties of QUIC described in [QUIC-INVARIANTS] to maximize its robustness to future versions of QUIC.

An arbitrary algorithmr MUST NOT make the routing behavior dependent on any bits in the first octet of the QUIC packet header, except the first bit, which indicates a long header. All other bits are QUIC version-dependent and intermediaries should not base their design on version-specific templates.

For example, one arbitrary algorithm might convert a non-compliant DCID to an integer and divided by the number of servers, with the modulus used to forward the packet. The number of servers is usually consistent on the time scale of a QUIC connection handshake. Another might simply hash the address/port 4-tuple. See also Section 10.

4.3. Server ID Allocation

For any given configuration, the configuration agent must specify if server IDs will be statically or dynamically allocated. Load Balancer configurations with statically allocated server IDs explicitly include a mapping of server IDs to forwarding addresses. The corresponding server configurations contain one or more unique server IDs.

A dynamically allocated configuration does not include any bespoke assignment, reducing configuration complexity. However, it places limits on the maximum server ID length and requires more state at the load balancer. In certain edge cases, it can force parts of the system to fail over to 5-tuple routing for a short time.

In either case, the configuration agent chooses a server ID length for each configuration that MUST be at least one octet. For Static Allocation, the maximum length depends on the algorithm. For dynamic allocation, the maximum length is 7 octets.

A QUIC-LB configuration MAY significantly over-provision the server ID space (i.e., provide far more codepoints than there are servers) to increase the probability that a randomly generated Destination Connection ID is non- compliant.

Conceptually, each configuration has its own set of server ID allocations, though two static configurations with identical server ID lengths MAY use a common allocation between them.

A server encodes one of its assigned server IDs in any CID it generates using the relevant configuration.

4.3.1. Static Allocation

In the manual allocation method, the configuration agent assigns at least one server ID to each server.

When forwarding a packet with a long header and non-compliant DCID, load balancers MUST forward packets with long headers and non-compliant DCIDs using an arbitrary algorithm as specified in Section 4.2.

4.3.2. Dynamic Allocation

In the dynamic allocation method, the load balancer assigns server IDs dynamically so that configuration does not require bespoke server ID assignment. This also reduces linkability. However, it requires state at the load balancer that roughly scales with the number of connections, until the server ID codespace is exhausted.

4.3.2.1. Configuration Agent Actions

The configuration agent does not assign server IDs, but does configure a server ID length and an "LB timeout". The server ID MUST be at least one and no more than seven octets.

4.3.2.2. Load Balancer Actions

The load balancer maintains a table of all assigned server IDs and corresponding routing information, which is initialized empty. These tables are independent for each operating configuration.

The load balancer MUST keep track of the most recent observation of each server ID, in any sort of packet it forwards, in the table and delete the entries when the time since that observation exceeds the LB Timeout.

Note that when the load balancer’s table for a configuration is empty, all incoming DCIDs corresponding to that configuration are non-compliant by definition.

The handling of a non-compliant long-header packet depends on the reason for non-compliance. The load balancer MUST applyt this logic:

* If the config rotation bits do not match a known configuration, the load balancer routes the packet using an arbitrary algorithm (see Section 4.2).

* If there is a matching configuration, but the CID is not long enough to apply the algorithm, the load balancer skips the first octet of the CID and then reads a server ID from the following octets, up to the server ID length. If this server ID matches a known server ID for that configuration, it forwards the packet accordingly and takes no further action. If it does not match, it routes using an arbitrary algorithm and adds the new server ID to that server’s table entry.

* If the sole reason for non-compliance is that the server ID is not in the load balancer's table, the load balancer routes the packet with an arbitrary algorithm. It adds the decoded server ID to table entry for the server the algorithm chooses and forwards the packet accordingly.

4.3.2.3. Server actions

Each server maintains a list of server IDs assigned to it, initialized empty. For each SID, it records the last time it received any packet with an CID that encoded that SID.

Upon receipt of a packet with a client-generated DCID, the server MUST follow these steps in order:

* If the config rotation bits do not correspond to a known configuration, do not attempt to extract a server ID.

* If the DCID is not long enough to decode using the configured algorithm, extract a number of octets equal to the server ID length, beginning with the second octet. If the extracted value does not match a server ID in the server's list, add it to the list.

* If the DCID is long enough to decode but the server ID is not in the server's list, add it to the list.

After any possible SID is extracted, the server processes the packet normally.

When a server needs a new connection ID, it uses one of the server IDs in its list to populate the server ID field of that CID. It SHOULD vary this selection to reduce linkability within a connection.

After loading a new configuration or long periods of idleness, a server may not have any available SIDs. This is because an incoming packet may not the config rotation bits necessary to extract a server ID in accordance with the algorithm above. When required to generate a CID under these conditions, the server MUST generate CIDs using the 5-tuple routing codepoint (see Section 3.2. Note that these connections will not be robust to client address changes while they use this connection ID. For this reason, a server SHOULD retire these connection IDs and replace them with routable ones once it receives a client-generated CID that allows it to acquire a server ID. As, statistically, one in every four such CIDs can provide a server ID, this is typically a short interval.

If a server has not received a connection ID encoding a particular server ID within the LB timeout, it MUST retire any outstanding CIDs that use that server ID and cease generating any new ones.

A server SHOULD have a mechanism to stop using some server IDs if the list gets large relative to its share of the codepoint space, so that these allocations time out and are freed for reuse by servers that have recently joined the pool.

5. Routing Algorithms

Encryption in the algorithms below uses the AES-128-ECB cipher. Future standards could add new algorithms that use other ciphers to provide cryptographic agility in accordance with [RFC7696]. QUIC-LB implementations SHOULD be extensible to support new algorithms.

5.1. Plaintext CID Algorithm

The Plaintext CID Algorithm makes no attempt to obscure the mapping of connections to servers, significantly increasing linkability. The format is depicted in the figure below.

```
Plaintext CID {
  First Octet (8),
  Server ID (8..128),
  For Server Use (8..152-len(Server ID)),
}
```

Figure 3: Plaintext CID Format

5.1.1. Configuration Agent Actions

For static SID allocation, the server ID length is limited to 16 octets. There are no parameters specific to this algorithm.

5.1.2. Load Balancer Actions

On each incoming packet, the load balancer extracts consecutive octets, beginning with the second octet. These bytes represent the server ID.

5.1.3. Server Actions

The server chooses how many octets to reserve for its own use, which MUST be at least one octet.

When a server needs a new connection ID, it encodes one of its assigned server IDs in consecutive octets beginning with the second. All other bits in the connection ID, except for the first octet, MAY be set to any other value. These other bits SHOULD appear random to observers.

5.2. Stream Cipher CID Algorithm

The Stream Cipher CID algorithm provides cryptographic protection at the cost of additional per-packet processing at the load balancer to decrypt every incoming connection ID. The CID format is depicted below.

```
Stream Cipher CID {
  First Octet (8),
  Nonce (64..120),
  Encrypted Server ID (8..128-len(Nonce)),
  For Server Use (0..152-len(Nonce)-len(Encrypted Server ID)),
}
```

Figure 4: Stream Cipher CID Format

5.2.1. Configuration Agent Actions

The configuration agent assigns a server ID to every server in its pool, and determines a server ID length (in octets) sufficiently large to encode all server IDs, including potential future servers.

The configuration agent also selects a nonce length and an 16-octet AES-ECB key to use for connection ID decryption. The nonce length MUST be at least 8 octets and no more than 16 octets. The nonce length and server ID length MUST sum to 19 or fewer octets, but SHOULD sum to 15 or fewer to allow space for server use.

5.2.2. Load Balancer Actions

Upon receipt of a QUIC packet, the load balancer extracts as many of the earliest octets from the destination connection ID as necessary to match the nonce length. The server ID immediately follows.

The load balancer decrypts the nonce and the server ID using the following three pass algorithm:

* Pass 1: The load balancer decrypts the server ID using 128-bit AES Electronic Codebook (ECB) mode, much like QUIC header protection. The encrypted nonce octets are zero-padded to 16 octets. AES-ECB encrypts this encrypted nonce using its key to generate a mask which it applies to the encrypted server id. This provides an intermediate value of the server ID, referred to as server-id intermediate.

server_id_intermediate = encrypted_server_id ^ AES-ECB(key, padded-encrypted-nonce)

* Pass 2: The load balancer decrypts the nonce octets using 128-bit AES ECB mode, using the server-id intermediate as "nonce" for this pass. The server-id intermediate octets are zero-padded to 16 octets. AES-ECB encrypts this padded server-id intermediate using its key to generate a mask which it applies to the encrypted nonce. This provides the decrypted nonce value.

nonce = encrypted_nonce ^ AES-ECB(key, padded-server_id_intermediate)

* Pass 3: The load balancer decrypts the server ID using 128-bit AES ECB mode. The nonce octets are zero-padded to 16 octets. AES-ECB encrypts this nonce using its key to generate a mask which it applies to the intermediate server id. This provides the decrypted server ID.

server_id = server_id_intermediate ^ AES-ECB(key, padded-nonce)

For example, if the nonce length is 10 octets and the server ID length is 2 octets, the connection ID can be as small as 13 octets. The load balancer uses the the second through eleventh octets of the connection ID for the nonce, zero-pads it to 16 octets, uses xors the result with the twelfth and thirteenth octet. The result is padded with 14 octets of zeros and encrypted to obtain a mask that is xored with the nonce octets. Finally, the nonce octets are padded with six octets of zeros, encrypted, and the first two octets xored with the server ID octets to obtain the actual server ID.

This three-pass algorithm is a simplified version of the FFX algorithm, with the property that each encrypted nonce value depends on all server ID bits, and each encrypted server ID bit depends on all nonce bits and all server ID bits. This mitigates attacks against stream ciphers in which attackers simply flip encrypted server-ID bits.

The output of the decryption is the server ID that the load balancer uses for routing.

5.2.3. Server Actions

When generating a routable connection ID, the server writes arbitrary bits into its nonce octets, and its provided server ID into the server ID octets. Servers MAY opt to have a longer connection ID beyond the nonce and server ID. The additional bits MAY encode additional information, but SHOULD appear essentially random to observers.

If the decrypted nonce bits increase monotonically, that guarantees that nonces are not reused between connection IDs from the same server.

The server encrypts the server ID using exactly the algorithm as described in Section 5.2.2, performing the three passes in reverse order.

5.3. Block Cipher CID Algorithm

The Block Cipher CID Algorithm, by using a full 16 octets of plaintext and a 128-bit cipher, provides higher cryptographic protection and detection of non-compliant connection IDs. However, it also requires connection IDs of at least 17 octets, increasing overhead of client-to-server packets.

```
Block Cipher CID {
  First Octet (8),
  Encrypted Server ID (8..128),
  Encrypted Bits for Server Use (128-len(Encrypted Server ID)),
  Unencrypted Bits for Server Use (0..24),
}
```

Figure 5: Block Cipher CID Format

5.3.1. Configuration Agent Actions

If server IDs are statically allocated, the server ID length MUST be no more than 12 octets, to provide servers adequate entropy to generate unique CIDs.

The configuration agent also selects an 16-octet AES-ECB key to use for connection ID decryption.

5.3.2. Load Balancer Actions

Upon receipt of a QUIC packet, the load balancer reads the first octet to obtain the config rotation bits. It then decrypts the subsequent 16 octets using AES-ECB decryption and the chosen key.

The decrypted plaintext contains the server id and opaque server data in that order. The load balancer uses the server ID octets for routing.

5.3.3. Server Actions

When generating a routable connection ID, the server MUST choose a connection ID length between 17 and 20 octets. The server writes its server ID into the server ID octets and arbitrary bits into the remaining bits. These arbitrary bits MAY encode additional information, and MUST differ between connection IDs. Bits in the eighteenth, nineteenth, and twentieth octets SHOULD appear essentially random to observers. The first octet is reserved as described in Section 3.

The server then encrypts the second through seventeenth octets using the 128-bit AES-ECB cipher.

6. ICMP Processing

For protocols where 4-tuple load balancing is sufficient, it is straightforward to deliver ICMP packets from the network to the correct server, by reading the echoed IP and transport-layer headers to obtain the 4-tuple. When routing is based on connection ID, further measures are required, as most QUIC packets that trigger ICMP responses will only contain a client-generated connection ID that contains no routing information.

To solve this problem, load balancers MAY maintain a mapping of Client IP and port to server ID based on recently observed packets.

Alternatively, servers MAY implement the technique described in Section 14.4.1 of [QUIC-TRANSPORT] to increase the likelihood a Source Connection ID is included in ICMP responses to Path Maximum Transmission Unit (PMTU) probes. Load balancers MAY parse the echoed packet to extract the Source Connection ID, if it contains a QUIC long header, and extract the Server ID as if it were in a Destination CID.

7. Retry Service

When a server is under load, QUICv1 allows it to defer storage of connection state until the client proves it can receive packets at its advertised IP address. Through the use of a Retry packet, a token in subsequent client Initial packets, and transport parameters, servers verify address ownership and clients verify that there is no on-path attacker generating Retry packets.

A "Retry Service" detects potential Denial of Service attacks and handles sending of Retry packets on behalf of the server. As it is, by definition, literally an on-path entity, the service must communicate some of the original connection IDs back to the server so that it can pass client verification. It also must either verify the address itself (with the server trusting this verification) or make sure there is common context for the server to verify the address using a service-generated token.

There are two different mechanisms to allow offload of DoS mitigation to a trusted network service. One requires no shared state; the server need only be configured to trust a retry service, though this imposes other operational constraints. The other requires a shared key, but has no such constraints.

Retry services MUST forward all QUIC packets that are not of type Initial or 0-RTT. Other packet types might involve changed IP addresses or connection IDs, so it is not practical for Retry Services to identify such packets as valid or invalid.

7.1. Common Requirements

Regardless of mechanism, a retry service has an active mode, where it is generating Retry packets, and an inactive mode, where it is not, based on its assessment of server load and the likelihood an attack is underway. The choice of mode MAY be made on a per-packet or per-connection basis, through a stochastic process or based on client address.

A configuration agent MUST distribute a list of QUIC versions the Retry Service supports. It MAY also distribute either an "Allow-List" or a "Deny-List" of other QUIC versions. It MUST NOT distribute both an Allow-List and a Deny-List.

The Allow-List or Deny-List MUST NOT include any versions included for Retry Service Support.

The Configuration Agent MUST provide a means for the entity that controls the Retry Service to report its supported version(s) to the configuration Agent. If the entity has not reported this information, it MUST NOT activate the Retry Service and the configuration agent MUST NOT distribute configuration that activates it.

The configuration agent MAY delete versions from the final supported version list if policy does not require the Retry Service to operate on those versions.

The configuration Agent MUST provide a means for the entities that control servers behind the Retry Service to report either an Allow-List or a Deny-List.

If all entities supply Allow-Lists, the consolidated list MUST be the union of these sets. If all entities supply Deny-Lists, the consolidated list MUST be the intersection of these sets.

If entities provide a mixture of Allow-Lists and Deny-Lists, the consolidated list MUST be a Deny-List that is the intersection of all provided Deny-Lists and the inverses of all Allow-Lists.

If no entities that control servers have reported Allow-Lists or Deny-Lists, the default is a Deny-List with the null set (i.e., all unsupported versions will be admitted). This preserves the future extensibilty of QUIC.

A retry service MUST forward all packets for a QUIC version it does not support that are not on a Deny-List or absent from an Allow-List. Note that if servers support versions the retry service does not, this may increase load on the servers.

Note that future versions of QUIC might not have Retry packets, require different information in Retry, or use different packet type indicators.

7.2. No-Shared-State Retry Service

The no-shared-state retry service requires no coordination, except that the server must be configured to accept this service and know which QUIC versions the retry service supports. The scheme uses the first bit of the token to distinguish between tokens from Retry packets (codepoint '0') and tokens from NEW_TOKEN frames (codepoint '1').

7.2.1. Configuration Agent Actions

See Section 7.1.

7.2.2. Service Requirements

A no-shared-state retry service MUST be present on all paths from potential clients to the server. These paths MUST fail to pass QUIC traffic should the service fail for any reason. That is, if the service is not operational, the server MUST NOT be exposed to client traffic. Otherwise, servers that have already disabled their Retry capability would be vulnerable to attack.

The path between service and server MUST be free of any potential attackers. Note that this and other requirements above severely restrict the operational conditions in which a no-shared-state retry service can safely operate.

Retry tokens generated by the service MUST have the format below.

```
Non-Shared-State Retry Service Token {
  Token Type (1) = 0,
  ODCIL (7) = 8..20,
  RSCIL (8) = 0..20,
  Original Destination Connection ID (64..160),
  Retry Source Connection ID (0..160),
  Opaque Data (..),
}
```

Figure 6: Format of non-shared-state retry service tokens

The first bit of retry tokens generated by the service MUST be zero. The token has the following additional fields:

ODCIL: The length of the original destination connection ID from the triggering Initial packet. This is in cleartext to be readable for the server, but authenticated later in the token. The Retry Service SHOULD reject any token in which the value is less than 8.

RSCIL: The retry source connection ID length.

Original Destination Connection ID: This also in cleartext and authenticated later.

Retry Source Connection ID: This also in cleartext and authenticated later.

Opaque Data: This data MUST contain encrypted information that allows the retry service to validate the client's IP address, in accordance with the QUIC specification. It MUST also provide a cryptographically secure means to validate the integrity of the entire token.

Upon receipt of an Initial packet with a token that begins with '0', the retry service MUST validate the token in accordance with the QUIC specification.

In active mode, the service MUST issue Retry packets for all Client initial packets that contain no token, or a token that has the first bit set to '1'. It MUST NOT forward the packet to the server. The service MUST validate all tokens with the first bit set to '0'. If

successful, the service MUST forward the packet with the token intact. If unsuccessful, it MUST drop the packet. The Retry Service MAY send an Initial Packet containing a CONNECTION_CLOSE frame with the INVALID_TOKEN error code when dropping the packet.

Note that this scheme has a performance drawback. When the retry service is in active mode, clients with a token from a NEW_TOKEN frame will suffer a 1-RTT penalty even though its token provides proof of address.

In inactive mode, the service MUST forward all packets that have no token or a token with the first bit set to '1'. It MUST validate all tokens with the first bit set to '0'. If successful, the service MUST forward the packet with the token intact. If unsuccessful, it MUST either drop the packet or forward it with the token removed. The latter requires decryption and re-encryption of the entire Initial packet to avoid authentication failure. Forwarding the packet causes the server to respond without the original_destination_connection_id transport parameter, which preserves the normal QUIC signal to the client that there is an on-path attacker.

7.2.3. Server Requirements

A server behind a non-shared-state retry service MUST NOT send Retry packets for a QUIC version the retry service understands. It MAY send Retry for QUIC versions the Retry Service does not understand.

Tokens sent in NEW_TOKEN frames MUST have the first bit set to '1'.

If a server receives an Initial Packet with the first bit set to '1', it could be from a server-generated NEW_TOKEN frame and should be processed in accordance with the QUIC specification. If a server receives an Initial Packet with the first bit to '0', it is a Retry token and the server MUST NOT attempt to validate it. Instead, it MUST assume the address is validated and MUST extract the Original Destination Connection ID and Retry Source Connection ID, assuming the format described in Section 7.2.2.

7.3. Shared-State Retry Service

A shared-state retry service uses a shared key, so that the server can decode the service's retry tokens. It does not require that all traffic pass through the Retry service, so servers MAY send Retry packets in response to Initial packets that don't include a valid token.

Both server and service must have access to Universal time, though tight synchronization is unnecessary.

The tokens are protected using AES128-GCM AEAD, as explained in Section 7.3.1. All tokens, generated by either the server or retry service, MUST use the following format, which includes:

* A 96 bit unique token number transmitted in clear text, but protected as part of the AEAD associated data.

* An 8 bit token key identifier.

* A token body, encoding the Original Destination Connection ID, the Retry Source Connection ID, and the Timestamp, optionally followed by server specific Opaque Data.

The token protection uses an 128 bit representation of the source IP address from the triggering Initial packet. The client IP address is 16 octets. If an IPv4 address, the last 12 octets are zeroes.

If there is a Network Address Translator (NAT) in the server infrastructure that changes the client IP, the Retry Service MUST either be positioned behind the NAT, or the NAT must have the token key to rewrite the Retry token accordingly. Note also that a host that obtains a token through a NAT and then attempts to connect over a path that does not have an identically configured NAT will fail address validation.

The 96 bit unique token number is set to a random value using a cryptography- grade random number generator.

The token key identifier and the corresponding AEAD key and AEAD IV are provisioned by the configuration agent.

The token body is encoded as follows:

```
Shared-State Retry Service Token Body {
   ODCIL (8) = 0..20,
   RSCIL (8) = 0..20,
   [Port (16)],
   Original Destination Connection ID (0..160),
   Retry Source Connection ID (0..160),
   Timestamp (64),
   Opaque Data (..),
}
```

Figure 7: Body of shared-state retry service tokens

The token body has the following fields:

ODCIL: The original destination connection ID length. Tokens in NEW_TOKEN frames MUST set this field to zero.

RSCIL: The retry source connection ID length. Tokens in NEW_TOKEN frames MUST set this field to zero.

Port: The Source Port of the UDP datagram that triggered the Retry packet. This field MUST be present if and only if the ODCIL is greater than zero. This field is therefore always absent in tokens in NEW_TOKEN frames.

Original Destination Connection ID: The server or Retry Service copies this from the field in the client Initial packet.

Retry Source Connection ID: The server or Retry service copies this from the Source Connection ID of the Retry packet.

Timestamp: The Timestamp is a 64-bit integer, in network order, that expresses the expiration time of the token as a number of seconds in POSIX time (see Sec. 4.16 of [TIME_T]).

Opaque Data: The server may use this field to encode additional information, such as congestion window, RTT, or MTU. The Retry Service MUST have zero-length opaque data.

Some implementations of QUIC encode in the token the Initial Packet Number used by the client, in order to verify that the client sends the retried Initial with a PN larger that the triggering Initial. Such implementations will encode the Initial Packet Number as part of the opaque data. As tokens may be generated by the Service, servers MUST NOT reject tokens because they lack opaque data and therefore the packet number.

7.3.1. Token Protection with AEAD

On the wire, the token is presented as:

```
Shared-State Retry Service Token {
  Unique Token Number (96),
  Key Sequence (8),
  Encrypted Shared-State Retry Service Token Body (80..),
  AEAD Checksum (length depends on encryption algorithm),
}
```

Figure 8: Wire image of shared-state retry service tokens

The tokens are protected using AES128-GCM as follows:

* The token key and IV are retrieved using the Key Sequence.

* The nonce, N, is formed by combining the IV with the 96 bit unique token number. The 96 bits of the unique token number are left-padded with zeros to the size of the IV. The exclusive OR of the padded unique token number and the IV forms the AEAD nonce.

* The associated data is a formatted as a pseudo header by combining the cleartext part of the token with the IP address of the client.

```
Shared-State Retry Service Token Pseudoheader {
  IP Address (128),
  Unique Token Number (96),
  Key Sequence (8),
}
```

Figure 9: Psuedoheader for shared-state retry service tokens

* The input plaintext for the AEAD is the token body. The output ciphertext of the AEAD is transmitted in place of the token body.

* The AEAD Checksum is computed as part of the AEAD encryption process, and is verified during decryption.

7.3.2. Configuration Agent Actions

The configuration agent generates and distributes a "token key", a "token IV", a key sequence, and the information described in Section 7.1.

7.3.3. Service Requirements

In inactive mode, the Retry service forwards all packets without further inspection or processing.

Retry services MUST NOT issue Retry packets except where explicitly allowed below, to avoid sending a Retry packet in response to a Retry token.

When in active mode, the service MUST generate Retry tokens with the format described above when it receives a client Initial packet with no token.

The service SHOULD decrypt incoming tokens. The service SHOULD drop packets with unknown key sequence, or an AEAD checksum that does not match the expected value. (By construction, the AEAD checksum will only match if the client IP Address also matches.)

If the token checksum passes, and the ODCIL and RSCIL fields are both zero, then this is a NEW_TOKEN token generated by the server. Processing of NEW_TOKEN tokens is subtly different from Retry tokens, as described below.

The service SHOULD drop a packet containing a token where the ODCIL is greater than zero and less than the minimum number of octets for a client-generated CID (8 in QUIC version 1). The service also SHOULD drop a packet containing a token where the ODCIL is zero and RSCIL is nonzero.

If the Timestamp of a token points to time in the past, the token has expired; however, in order to allow for clock skew, it SHOULD NOT consider tokens to be expired if the Timestamp encodes a few seconds in the past. An active Retry service SHOULD drop packets with expired tokens. If a NEW_TOKEN token, the service MUST generate a Retry packet in response. It MUST NOT generate a Retry packet in response to an expired Retry token.

If a Retry token, the service SHOULD drop packets where the port number encoded in the token does not match the source port in the encapsulating UDP header.

All other packets SHOULD be forwarded to the server.

7.3.4. Server Requirements

When issuing Retry or NEW_TOKEN tokens, the server MUST include the client IP address in the authenticated data as specified in Section 7.3.1. The ODCIL and RSCIL fields are zero for NEW_TOKEN tokens, making them easily distinguishable from Retry tokens.

The server MUST validate all tokens that arrive in Initial packets, as they may have bypassed the Retry service.

For Retry tokens that follow the format above, servers SHOULD use the timestamp field to apply its expiration limits for tokens. This need not be precisely synchronized with the retry service. However, servers MAY allow retry tokens marked as being a few seconds in the past, due to possible clock synchronization issues.

After decrypting the token, the server uses the corresponding fields to populate the original_destination_connection_id transport parameter, with a length equal to ODCIL, and the retry_source_connection_id transport parameter, with length equal to RSCIL.

For QUIC versions the service does not support, the server MAY use any token format.

As discussed in [QUIC-TRANSPORT], a server MUST NOT send a Retry packet in response to an Initial packet that contains a retry token.

8. Configuration Requirements

], [illegible] format.

Appendix A provides a YANG Model of the a full QUIC-LB configuration.

9. Additional Use Cases

This section discusses considerations for some deployment scenarios not implied by the specification above.

9.1. Load balancer chains

Some network architectures may have multiple tiers of low-state load balancers, where a first tier of devices makes a routing decision to the next tier, and so on, until packets reach the server. Although QUIC-LB is not explicitly designed for this use case, it is possible to support it.

If each load balancer is assigned a range of server IDs that is a subset of the range of IDs assigned to devices that are closer to the client, then the first devices to process an incoming packet can extract the server ID and then map it to the correct forwarding address. Note that this solution is extensible to arbitrarily large numbers of load-balancing tiers, as the maximum server ID space is quite large.

9.2. Moving connections between servers

Some deployments may transparently move a connection from one server to another. The means of transferring connection state between servers is out of scope of this document.

To support a handover, a server involved in the transition could issue CIDs that map to the new server via a NEW_CONNECTION_ID frame, and retire CIDs associated with the new server using the "Retire Prior To" field in that frame.

Alternately, if the old server is going offline, the load balancer could simply map its server ID to the new server’s address.

10. Version Invariance of QUIC-LB

Non-shared-state Retry Services are inherently dependent on the format (and existence) of Retry Packets in each version of QUIC, and so Retry Service configuration explicitly includes the supported QUIC versions.

The server ID encodings, and requirements for their handling, are designed to be QUIC version independent (see [QUIC-INVARIANTS]). A QUIC-LB load balancer will generally not require changes as servers deploy new versions of QUIC. However, there are several unlikely future design decisions that could impact the operation of QUIC-LB.

The maximum Connection ID length could be below the minimum necessary for one or more encoding algorithms.

Section 4.1 provides guidance about how load balancers should handle non-compliant DCIDs. This guidance, and the implementation of an algorithm to handle these DCIDs, rests on some assumptions:

* Incoming short headers do not contain DCIDs that are client-generated.

* The use of client-generated incoming DCIDs does not persist beyond a few round trips in the connection.

* While the client is using DCIDs it generated, some exposed fields (IP address, UDP port, client-generated destination Connection ID) remain constant for all packets sent on the same connection.

* Dynamic server ID allocation is dependent on client-generated Destination CIDs in Initial Packets being at least 8 octets in length. If they are not, the load balancer may not be able to extract a valid server ID to add to its table. Configuring a shorter server ID length can increase robustness to a change.

While this document does not update the commitments in [QUIC-INVARIANTS], the additional assumptions are minimal and narrowly scoped, and provide a likely set of constants that load balancers can use with minimal risk of version- dependence.

If these assumptions are invalid, this specification is likely to lead to loss of packets that contain non-compliant DCIDs, and in extreme cases connection failure.

Some load balancers might inspect elements of the Server Name Indication (SNI) extension in the TLS Client Hello to make a routing decision. Note that the format and cryptographic protection of this information may change in future versions or extensions of TLS or QUIC, and therefore this functionality is inherently not version-invariant.

11. Security Considerations

QUIC-LB is intended to prevent linkability. Attacks would therefore attempt to subvert this purpose.

Note that the Plaintext CID algorithm makes no attempt to obscure the server mapping, and therefore does not address these concerns. It exists to allow consistent CID encoding for compatibility across a network infrastructure, which makes QUIC robust to NAT rebinding. Servers that are running the Plaintext CID algorithm SHOULD only use it to generate new CIDs for the Server Initial Packet and SHOULD NOT send CIDs in QUIC NEW_CONNECTION_ID frames, except that it sends one new Connection ID in the event of config rotation Section 3.1. Doing so might falsely suggest to the client that said CIDs were generated in a secure fashion.

A linkability attack would find some means of determining that two connection IDs route to the same server. As described above, there is no scheme that strictly prevents linkability for all traffic patterns, and therefore efforts to frustrate any analysis of server ID encoding have diminishing returns.

11.1. Attackers not between the load balancer and server

Any attacker might open a connection to the server infrastructure and aggressively simulate migration to obtain a large sample of IDs that map to the same server. It could then apply analytical techniques to try to obtain the server encoding.

The Stream and Block Cipher CID algorithms provide robust protection against any sort of linkage. The Plaintext CID algorithm makes no attempt to protect this encoding.

Were this analysis to obtain the server encoding, then on-path observers might apply this analysis to correlating different client IP addresses.

11.2. Attackers between the load balancer and server

Attackers in this privileged position are intrinsically able to map two connection IDs to the same server. The QUIC-LB algorithms do prevent the linkage of two connection IDs to the same individual connection if servers make reasonable selections when generating new IDs for that connection.

11.3. Multiple Configuration IDs

During the period in which there are multiple deployed configuration IDs (see Section 3.1), there is a slight increase in linkability. The server space is effectively divided into segments with CIDs that have different config rotation bits. Entities that manage servers SHOULD strive to minimize these periods by quickly deploying new configurations across the server pool.

11.4. Limited configuration scope

A simple deployment of QUIC-LB in a cloud provider might use the same global QUIC-LB configuration across all its load balancers that route to customer servers. An attacker could then simply become a customer, obtain the configuration, and then extract server IDs of other customers' connections at will.

To avoid this, the configuration agent SHOULD issue QUIC-LB configurations to mutually distrustful servers that have different keys for encryption algorithms. The load balancers can distinguish these configurations by external IP address, or by assigning different values to the config rotation bits (Section 3.1). Note that either solution has a privacy impact; see Section 11.3.

These techniques are not necessary for the plaintext algorithm, as it does not attempt to conceal the server ID.

11.5. Stateless Reset Oracle

Section 21.9 of [QUIC-TRANSPORT] discusses the Stateless Reset Oracle attack. For a server deployment to be vulnerable, an attacking client must be able to cause two packets with the same Destination CID to arrive at two different servers that share the same cryptographic context for Stateless Reset tokens. As QUIC-LB requires deterministic routing of DCIDs over the life of a connection, it is a sufficient means of avoiding an Oracle without additional measures.

11.6. Connection ID Entropy

The Stream Cipher and Block Cipher algorithms need to generate different cipher text for each generated Connection ID instance to protect the Server ID. To do so, at least four octets of the Block Cipher CID and at least eight octets of the Stream Cipher CID are reserved for a nonce that, if used only once, will result in unique cipher text for each Connection ID.

If servers simply increment the nonce by one with each generated connection ID, then it is safe to use the existing keys until any server's nonce counter exhausts the allocated space and rolls over to zero. Whether or not it implements this method, the server MUST NOT reuse a nonce until it switches to a configuration with new keys.

Configuration agents SHOULD implement an out-of-band method to discover when servers are in danger of exhausting their nonce space, and SHOULD respond by issuing a new configuration. A server that has exhausted its nonces MUST either switch to a different configuration, or if none exists, use the 4-tuple routing config rotation codepoint.

11.7. Shared-State Retry Keys

The Shared-State Retry Service defined in Section 7.3 describes the format of retry tokens or new tokens protected and encrypted using AES128-GCM. Each token includes a 96 bit randomly generated unique token number, and an 8 bit identifier of the AES-GCM encryption key. There are three important security considerations for these tokens:

* An attacker that obtains a copy of the encryption key will be able to decrypt and forge tokens.

* Attackers may be able to retrieve the key if they capture a sufficently large number of retry tokens encrypted with a given key.

* Confidentiality of the token data will fail if separate tokens reuse the same 96 bit unique token number and the same key.

To protect against disclosure of keys to attackers, service and servers MUST ensure that the keys are stored securely. To limit the consequences of potential exposures, the time to live of any given key should be limited.

Section 6.6 of [QUIC-TLS] states that "Endpoints MUST count the number of encrypted packets for each set of keys. If the total number of encrypted packets with the same key exceeds the confidentiality limit for the selected AEAD, the endpoint MUST stop using those keys." It goes on with the specific limit: "For AEAD_AES_128_GCM and AEAD_AES_256_GCM, the confidentiality limit is 2^23 encrypted packets; see Appendix B.1." It is prudent to adopt the same limit here, and configure the service in such a way that no more than 2^23 tokens are generated with the same key.

In order to protect against collisions, the 96 bit unique token numbers should be generated using a cryptographically secure pseudorandom number generator (CSPRNG), as specified in Appendix C.1

of the TLS 1.3 specification [RFC8446]. With proper random numbers, if fewer than 2^40 tokens are generated with a single key, the risk of collisions is lower than 0.001%.

12. IANA Considerations

There are no IANA requirements.

```

Appendix B. Load Balancer Test Vectors

Each section of this draft includes multiple sets of load balancer configuration, each of which has five examples of server ID and server use bytes and how they are encoded in a CID.

In some cases, there are no server use bytes. Note that, for simplicity, the first octet bits used for neither config rotation nor length self-encoding are random, rather than listed in the server use field. Therefore, a server implementation using these parameters may generate CIDs with a slightly different first octet.

This section uses the following abbreviations:

cid	Connection ID
cr_bits	Config Rotation Bits
LB	Load Balancer
sid	Server ID
sid_len	Server ID length
su	Server Use Bytes

All values except length_self_encoding and sid_len are expressed in hexidecimal format.

B.1. Plaintext Connection ID Algorithm

```
LB configuration: cr_bits 0x0 length_self_encoding: y sid_len 1

cid 01be sid be su
cid 0221b7 sid 21 su b7
cid 03cadfd8 sid ca su dfd8
cid 041e0c9328 sid 1e su 0c9328
cid 050c8f6d9129 sid 0c su 8f6d9129

LB configuration: cr_bits 0x0 length_self_encoding: n sid_len 2

cid 02aab0 sid aab0 su
cid 3ac4b106 sid c4b1 su 06

Appendix C. Acknowledgments

The authors would like to thank Christian Huitema and Ian Swett for their major design contributions.

Manasi Deval, Erik Fuller, Toma Gavrichenkov, Jana Iyengar, Subodh Iyengar, Ladislav Lhotka, Jan Lindblad, Ling Tao Nju, Kazuho Oku, Udip Pant, Martin Thomson, Dmitri Tikhonov, Victor Vasiliev, and William Zeng Ke all provided useful input to this document.

Appendix D. Change Log

RFC Editor's Note: Please remove this section prior to publication of a final version of this document.

D.1. since draft-ietf-quic-load-balancers-05

* Added low-config CID for further discussion
* Complete revision of shared-state Retry Token
* Added YANG model
* Updated configuration limits to ensure CID entropy
* Switched to notation from quic-transport

D.2. since draft-ietf-quic-load-balancers-04

* Rearranged the shared-state retry token to simplify token processing
* More compact timestamp in shared-state retry token
* Revised server requirements for shared-state retries
* Eliminated zero padding from the test vectors
* Added server use bytes to the test vectors
* Additional compliant DCID criteria

D.3. since-draft-ietf-quic-load-balancers-03

* Improved Config Rotation text
* Added stream cipher test vectors

* Deleted the Obfuscated CID algorithm

D.4. since-draft-ietf-quic-load-balancers-02

* Replaced stream cipher algorithm with three-pass version
* Updated Retry format to encode info for required TPs
* Added discussion of version invariance

D.9. Since draft-duke-quic-load-balancers-04

* Added standard for retry services

D.10. Since draft-duke-quic-load-balancers-03

* Renamed Plaintext CID algorithm as Obfuscated CID
* Added new Plaintext CID algorithm
* Updated to allow 20B CIDs
* Added self-encoding of CID length

D.11. Since draft-duke-quic-load-balancers-02

* Added Config Rotation
* Added failover mode
* Tweaks to existing CID algorithms
* Added Block Cipher CID algorithm
* Reformatted QUIC-LB packets

D.12. Since draft-duke-quic-load-balancers-01

* Complete rewrite
* Supports multiple security levels
* Lightweight messages

D.13. Since draft-duke-quic-load-balancers-00

* Converted to markdown
* Added variable length connection IDs
